ABSTRACT

We propose a new programming control structure called “multifor”, allowing to take advantage of parallelization models that were not naturally attainable with the polytope model before. In a multifor-loop, several loops whose bodies are run simultaneously can be defined. Respective iteration domains are mapped onto each other according to a run frequency – the grain – and a relative position – the offset –. Execution models like dataflow, stencil computations or MapReduce can be represented onto one referential iteration domain, while still exhibiting traditional polyhedral code analysis and transformation opportunities. Moreover, this construct provides ways to naturally exploit hybrid parallelization models, thus significantly improving parallelization opportunities in the multicore era. Traditional polyhedral software tools are used to generate the corresponding code. Additionally, a promising perspective related to nonlinear mapping of iteration spaces is also presented, yielding to run a loop nest inside any other one by solving the problem of inverting “ranking Ehrhart polynomials”.

programming control structure, parallel programming, polytope model

1. INTRODUCTION

We have definitely entered a new era in programming. Parallelism is everywhere, from the many-core processor architectures that are from now on fitting mainstream computers, to the software applications that are now mixing intensive computations, specialized routines, network communication and multi-threading. Many researches focus in proposing new languages supposed to facilitate programming inside this complex environment [8, 10, 11, 13], or in proposing hardware or software support like transactional memory systems [6, 14, 15], supposed to prevent incorrect computations while still providing good performance. However, all these proposals face intractable issues. Most proposed languages imply to change drastically programmers habits and have weak chances to be adopted by the software industry [4]. Moreover, even if they offer interesting constructions to express parallel tasks, they are not solving the fundamental problem of correct and efficient parallelism extraction, which induces dependency analysis, data locality optimization, task grain adjustment, etc. Performance is also strongly dependent of their implementation, i.e. of their compilers or runtime systems. On the other hand, hardware or software support does not either result in hiding parallelization complexity to the user. And overall, these mechanisms are of high complexity by themselves, which mostly often make them unrealistic for a real usage [3].

Nevertheless, parallel programming has already a long history, where gradual extensions have been proposed. Some of them were pretty successful and are still current. For example, directive-based languages, as OpenMP [2], are extensions to mainstream languages. The use of their instructions is not mandatory when inserted in a source code, and they can be discovered and adopted progressively by any developer. They are not breaking the programming habits, while offering efficient parallelization opportunities. Although they are not solving either the fundamental complexity of parallelization, they nicely open the door of high performance computing to anyone.

At the same time, a lot of relevant transformation techniques have been discovered in order to exhibit parallelism or to optimize code, particularly on loops, as software pipelining, loop unrolling, tiling, skewing, etc [1, 16, 12]. These are applied either by experienced programmers, or automatically by compilers or optimization tools. In the parallelism era, compilers and runtime systems have to accelerate their progresses in automatic parallelization, but at the same time, programmers have to be brought to become, at least, who we called “experienced programmers” ten or twenty years ago.

We argue that a good way to achieve such an emancipation to parallel programming is to gradually extend mainstream languages with new programming control structures
that are derived from already existing ones. Our idea is that
many well-known optimizing and parallelizing code transfor-
mations should now be applied naturally by developers, but
only in their minds, while using a control structure translat-
ing their enriched algorithmic reasonings. The existence of
such control structures will condition them to enlarge their
way of reasoning while programming. In the same way that
it is currently natural to express the repetition of code blocks
by using loops, or to abstract parametrized code by using
functions, it should now be natural to bring closer instruc-
tions that are using the same operands, or to arrange code
snippets in vertical and horizontal directions to express si-
multaneity, sequencing and overlapping.

Following this idea, we propose a new control structure
called Multifor, which can be seen as an extension of for-
loops to multiple for-loops running at the same time, whose
respective instructions are run sequentially inside one loop
body as a traditional for-loop, but run in any interleaved
order, or in parallel, between the bodies. Additionally to
traditional parameters as indices, bounds and steps, we pro-
pose to introduce a grain and an offset, allowing to mix loops
diff erent execution frequencies and of different starting
positions. Such programming construct translates natu-
 rally to code transformations as loop fusion, loop pipelining
or loop partitioning. Moreover, it facilitates many code op-
timizations as data locality improvement or parallelization.
It can be seen as an extension of for-loops from “vertical” to
“horizontal” programming.

The second motivation of this proposal is related to the
parallel programming models that are covered by the poly-
tope model. Traditional application of this model does not
allow to naturally express parallel programming models as
task parallelism, dataflow or MapReduce. We show that
the multifor construct allows to schedule loop nest processes
by mapping together their respective iteration domains. A
multifor code can be represented geometrically by a partic-
ular union of polyhedra, each being previously dilated, com-
pressed or translated, either entirely or partially, according
to transformation factors defined by constants or affine func-
tions.

This new programming structure implies interesting im-
plementation challenges for a compiler, from its front-end to
its backend. We show that, as it is already the case with
for-loops, the polytope model is quite well adapted to anal-
yze, optimize and translate multifor constructs into effi-
cient code.

Finally, as a promising perspective, we also propose a non-
linear mapping of the iteration domains guided by the ranks
of the iterations. This approach opens the possibility of
mapping any iteration domain onto any other domain with-
out being constrained by their shapes. It leads to solve the
general problem of executing any loop nest by any other
loop nest of the same trip count. Mathematically speaking,
the general solution to this problem is based on inverting
“ranking Ehrhart polynomials” [5, 9].

The paper is organized as follows. In the next section,
syntax and semantics of multifor loops are described, illus-
trated with a few examples of multifor headers and graphical
representations. We also highlight the code parallelization
and transformation schemes that are possible with multifor-
loops. In Section 3, we discuss the main issues related to
the implementation of multifor constructs and their corre-
sponding code generation. Several real and representative
code examples are presented in Section 4, highlighting the
interesting contributions of this new control structure. The
promising perspective of non-linear iteration space mapping
is the topic of Section 5, where a solution for inverting rank-
ing Ehrhart polynomials is proposed. Finally, conclusions
and further perspectives are given in Section 6.

2. SYNTAX AND SEMANTICS

In this paper, we describe the initial syntax and seman-
tics for the multifor construct. However, they can be ex-
tended in many ways in the future. We first present the
case of one unique multifor construct, as the case of nested
multifor-loops present some specificities which are presented
afterwards.

2.1 Non-nested multifor-loops

The multifor syntax is defined by:

\[
\text{multifor} \begin{pmatrix}
\text{index}_1 = \text{expr}, [\text{index}_2 = \text{expr}, ...];
\text{index}_1 < \text{expr}, [\text{index}_2 < \text{expr}, ...];
\text{index}_1 + = \text{cst}, [\text{index}_2 + = \text{cst}, ...];
\text{grain}_1, [\text{grain}_2, ...];
\text{offset}_1, [\text{offset}_2, ...] \end{pmatrix}
\}
\begin{pmatrix}
\text{prefix} : \{ \text{statements} \}
\end{pmatrix}
\]

where [...] denotes optional arguments, index, denotes the
indices of the loops composing the multifor, expr denotes
affine arithmetic expressions on enclosing loop indices, or
constants, cst denotes an integer constant, grain and offset
are positive integers, grain \( \geq 1 \), offset \( \geq 0 \), and prefix is a
positive integer associating each statement to a given for-
loop composing the multifor-loop, according to the order in
which they are defined (0 for the first loop, 1 for the second
loop, etc.). Without loss of generality, we consider in the
following that the index steps, cst, always equal one, since
the general case can be easily deduced.

Each for-loop composing the multifor behaves as a tradi-
tional for-loop, but all are mapped on a same global “virtual
referential” domain, which can also be seen as a template.
The way iterations of the for-loops are mapped is defined by
their respective offset and grain. The grain defines the
frequency in which the associated loop has to run, relative-
to the referential. For instance, if the grain equals 2, then
one iteration of the associated loop will run over 2 iterations
of the referential. The offset defines the gap between the
first iteration of the referential and the first iteration of the
associated loop. For instance, if the offset equals 3, then the
first iteration of the associated loop will run at the fourth
iteration of the referential loop.

The size and shape of the referential is deduced from the
for-loops composing the multifor-loop. Geometrically, it is
declared as the disjoint union of the for-loop domains, where
each domain has been previously shifted according to its off-
set and dilated according to its grain. The disjoint union is
the union of adjacent convex domains, each being scanned
by a referral for-loop. The relative positions of the it-
erations of the for-loops composing the multifor-loop inside
the referential depends of the overlapping of their respec-
tive domains. It means that on domains where only one
for-loop iterations are run, the grain becomes a compression
factor. In general, the greatest common divisor of the grains
of all the for-loops overlapping on a same referential domain

2.2 Nested multifor-loops
2.2 Nested multifor-loops

Nested multifor-loops present particularities and specific semantics has to be described. Without loss of generality, let us consider two nested multifor-loops composed of two for-loop nests:

\[
\text{multifor}(i_1, j_1) = \{ \text{for } i_1 \text{ do } \ldots \text{end for} \}
\]
\[
\text{multifor}(i_2, j_2) = \{ \text{for } i_2 \text{ do } \ldots \text{end for} \}
\]

Such a nest behaves as two for-loop nests, \((i_1, j_1)\) and \((i_2, j_2)\), respectively running simultaneously in the same way as it is for one unique multifor-loop. The grain of the inner multifor-loop introduces a delay for the iteration of the inner multifor-loop, which is computed by the grain and the offset. Another example is:

\[
\text{multifor}(i_1, j_1) = \{ \text{for } i_1 \text{ do } \ldots \text{end for} \}
\]
\[
\text{multifor}(i_2, j_2) = \{ \text{for } i_2 \text{ do } \ldots \text{end for} \}
\]

Notice that the index values have no effect on the relative positions of the for-loops bodies, which are uniquely determined by the grain and the offset. Without loss of generality, let us consider two simple multifor-loops composed of two for-loop nests:

\[
\text{multifor}(i_1, j_1) = \{ \text{for } i_1 \text{ do } \ldots \text{end for} \}
\]
\[
\text{multifor}(i_2, j_2) = \{ \text{for } i_2 \text{ do } \ldots \text{end for} \}
\]

Now, the behavior is illustrated by the figure below:

In this example, the offset of index \(i_1\) is zero, and the one of index \(i_2\) is 2. Thus, the first iteration of the \(i_2\)-loop will run immediately, while the first iteration of the \(i_2\)-loop will run after the 3rd iteration of the \(i_1\)-loop, but with \(i_1 = 0\).

2.3 Multifor-loop parallelization and code transformations

The multifor construct exhibits a straightforward parallelism structure which is not trivial to exploit. The model of parallelism provides new opportunities to the polyhedral model, since it enables the expression of parallel strategies on code examples in Section 4.

Nevertheless, the multifor construct still allows OpenMP-like parallelization strategies.
Moreover, each for-loop, or for-loop nest, of a multifor, can be transformed using any well-known polyhedral transformation. However, in the context of a multifor, these transformations may be guided by the interactions between the for-loops, in order to achieve better performance or better data locality for instance. Another opportunity is the transformation of imperfect loop nests into multifor-loop nests of perfectly nested loops.

### 3. IMPLEMENTATION ISSUES

#### 3.1 Reference domain

Consider one multifor-loop level. The referential for-loops cadencing the multifor execution have the constraint of scanning a sufficient number of iterations. Let us denote by \( f \) the number of for-loops. By computing the disjoint union of all for-loops iteration domains, we obtain a set of adjacent domains \( D_i \) on which some of the \( f \) loops overlap. Let us denote by \( lb_i, ub_i, grain_i \), and \( offset_i \), \( i = 1..f \) the parameters characterizing each for-loop in the multifor header. We set \( nb_l = \text{offset}_i \), and \( nu_l = (ub_i - lb_i + 1) \times grain_i + \text{offset}_i \), which define the lower and upper bounds of each loop in the referential domain, since the computation of \( nb_l \) consists in translating the domain and the computation of \( nu_l \) in dilating the domain by a factor which equals the grain. The disjoint union of \( D_i \)'s is computed using these latter bounds. The initial index value of the referential domain is \( MIN_{i=1..f}(nb_l) \). Hence, the total number of iterations in the referential domain, before compression, is:

\[
MAX_{i=1..f}(nb_l) - MIN_{i=1..f}(nb_l) + 1
\]

In order to generate the referential for-loops for each domain \( D_i \), the last step consists in compressing each \( D_i \) by a factor defined by \( \text{lcm}(grain_i) \), for all loops \( j \) overlapping on \( D_i \).

More generally for any multifor-loop nest, the computation of the referential loop is performed in three steps. First, each iteration domain associated to one for-loop nest composing a multifor-loop nest is translated from the origin according to its offsets, and dilated according to its grains in every dimension. Notice that values actually taken by the indices of the for-loop nests are not defining their positions in the referential domain. Second, a disjoint union is computed and resulting in a union of adjacent convex domains \( D_i \). Third, each \( D_i \) may be compressed according to the greatest common divisor of the grains of the associated for-loop nests, and according to the lexicographic order.

#### 3.2 Code generation

When considering sequential code, there are two dual ways to generate the code corresponding to a multifor-loop nest. A first way is to generate loop nests scanning the referential domains through a minimal set of convex domains, and to insert guards in their bodies in order to execute the convenient instructions at each iteration. The number of these guards can be optimized by computing their common sub-domains. The second way is to scan each \( D_i \) using a dedicated loop nest with a constant loop body, without guards.

Both solutions can be generated automatically using polytope model tools like PolyLib or CLooG, and by inserting phases to compute the translated and dilated domains, or to compress parts of the resulting referential domains.

If for-loops of given depth of a multifor-loop nest have to be run in parallel, each for-loop has to be run in a separated thread and all threads have to be synchronized at the multifor-loop completion. Notice that this could be enriched by providing OpenMP-like options as NOWAIT.

Original indices of the multifor \((i_1, i_2, j_1, ...)\) have to be retrieved at the beginning of each loop body, by being computed from the referential loop indices. These computations consists in subtracting offsets, or in adding modules of the referential loop indices relatively to grains, or in multiplying by grains in case of compressed domains.

### 4. EXAMPLES

**Sobel edge detection:** We first consider the code for performing Sobel edge detection of an image shown in Figure 1. The first loop nest of this program reads the input image, while the second loop nest performs the actual edge detection and writes out the output image.

Note that nine neighboring elements have to be read before its resulting pixel can be computed and written. Hence both loop nests can be naturally overlapped by writing the code using the multifor construct exhibiting a data-flow model of computation, shown in Figure 2. The associated referential domain is shown in Figure 3.

**Red-Black Gauss-Seidel:** The second example is the Red-Black Gauss-Seidel algorithm composed of two phases. The first phase consists in updating the red elements of a grid, which are one point over two in the \( i \) and \( j \) directions of the grid, starting from the first bottom left corner, using their North-South-East-West (NSEW) neighbors, which are black elements. The second phase consists obviously in updating the black elements from the red ones. For a 2D \( N \times N \) problem, the usual code, is of the form shown in Figure 4 (the border elements initialization has been omitted).
each phase one after the other. The multifor strategy can consist in parallelizing each of the phases, and to execute parallelism in this case – since the traditional parallelization dependency vectors which are now allowing a linear schedule of iterations is active. Moreover, the NSEW dependencies prevent any linear parallel schedule. This code can be translated into a multifor-loop nest with the red and black phases each yield two for-loop nests with convenient grains and offsets as shown in Figure 5.

The referential initial domain of the multifor code is represented in Figure 6 on the left, also showing the transformed dependency vectors which are now allowing a linear schedule. On the right in Figure 6, the final iteration domains, after compression, are represented.

This example shows that the multifor construct allows to exploit different kind of parallelism – the so-called wavefront parallelism in this case – since the traditional parallelization consists in parallelizing each of the phases, and to execute each phase one after the other. The multifor strategy can be preferable to improve data locality and thus improve the resulting execution time. Here, some parallelism within the red points and within the black points can still be exploited, but also parallelism between red and black points. As an example, we show as a source code the sequential code that could be generated from this multifor-loop nest in Figure 7.

Figure 5: Red-Black Gauss-Seidel multifor code

Figure 6: Red-Black Gauss-Seidel referential domain

Figure 7: Red-Black Gauss-Seidel generated code

Matrix product by blocks: The third example is an algorithm to compute the product of two matrices $n \times n$, $(A \times B = C)$, by partitioning the matrices into uniform blocks. The matrix product is then carried out block by block. We split the two matrices $A$ and $B$ as follows:

- matrix $A$ is divided into two matrices $A_1$ and $A_2$ whose dimension is $n/2 \times n$.
- matrix $B$ is divided into two matrices $B_1$ and $B_2$ whose dimension is $n \times n/2$.

The product $A \times B = C$ translates to four products: $A_1 \times B_1 = C_1, A_1 \times B_2 = C_2, A_2 \times B_1 = C_3$ and $A_2 \times B_2 = C_4$, i.e.,

$$
\begin{pmatrix}
A_1 \\
A_2
\end{pmatrix}
\times
\begin{pmatrix}
B_1 \\
B_2
\end{pmatrix}
= 
\begin{pmatrix}
C_1 \\
C_2 \\
C_3 \\
C_4
\end{pmatrix}
$$
Since each for-loop nest computes a 1D expression, the execution scheme corresponds to the MapReduce strategy. If the width and the height of the hidden image $HWidth$ and $HHeight$ are from an enclosing one. It is assumed that the upper left of a steganography code where an hidden image is extracted. The fourth example is the decoding phase.

**Multifor matrix product code**

The dimension of matrices $C_1$, $C_2$, $C_3$ and $C_4$ is $(n/2 \times n/2)$. These four products might be performed simultaneously and can be naturally expressed using the multifor structure as shown in figure 8.

Geometrically, the multifor iteration domain is a $(n/2 \times n/2 \times n)$ rectangle parallelepiped where each point is associated to four iterations of the four included loop-nests. This execution scheme corresponds to the MapReduce strategy since each for-loop nest computes a $n/2 \times n/2$ sub-block (map step), and the combination of all sub-blocks forms the resulting matrix $C$ (reduce step).

**Steganography:** The fourth example is the decoding phase of a steganography code where an hidden image is extracted from an enclosing one. It is assumed that the upper left pixel of the hidden image is hidden within the upper left pixel of the enclosing image; $HWidth$ and $HHeight$ are the width and the height of the hidden image; $EWidth$ and $EHeight$ are the width and the height of the enclosing image; $EImage$ is the image hiding another image; $HImage$ is the extracted output image that was hidden; $MImage$ is the output encoding image hiding no more the image that was hidden in $EImage$. The proposed multifor code version is composed of four simultaneous for-loop nests, the first being dedicated to the extraction of the hidden image, the second to the extraction of the part of the enclosing image which is hiding the hidden image, the third and the fourth being dedicated to copy the pixels directly to the retrieved enclosing image. Since the union of the third and fourth domain is not convex, two loop-nests are necessary to scan it. Notice that we introduce a shortcut in the syntax such that similar loop bodies can be instantiated differently depending on their associated loop-nest. The multifor code is shown in Figure 9 and a view of the enclosing and hidden images, and how the multifor-loop nest scan them is shown in Figure 10. Notice that full parallelism is exhibited with this code.

**Secret key cryptosystem**

The fifth example is a classic secret key cryptosystem that manipulates binary words. It proceeds by splitting a message $m$ into blocks of constant size. These cryptosystems are characterized by the length of each block, the operating mode and the encryption system of each block. Each cipher mode comprises:

1. Cutting in many blocks $m_1,...,m_k$ the plain text message $m$;
2. Encrypting the blocks $m_i$ resulting in the encrypted blocks $c_1,...,c_k$;
3. Concatenating the blocks $c_1,...,c_k$ to construct the encrypted message $c$.

Each block is encrypted through the product of two cryptosystems $T_1$ and $T_2$. It is classically computed using a loop of the form:

```cpp
for (i = 0; i < k; i++) {
    c[i] = Encrypt(m[i], T_1);
    c[i] = Encrypt(c[i], T_2);
}
```

Suppose the encryption of each block by a given cryptosystem consumes one unit of time. The time required to encrypt the entire message using this loop is $2 \times k$. Let us write this code using a multifor structure:
5. A PROMISING PERSPECTIVE: NON-LINEAR MAPPING

Among the numerous possible extensions, an important one is to map iteration spaces together following a non-linear fashion, such that their shapes have no influence in the mapping. In general, this would allow to execute iterations of any loop nest by any other one of the same trip count, and thus to enlarge significantly the way iterations of different loops can be mapped together. Hence a multifor construct could express quite different computations in a concise way, and augment the number of optimization and parallelization opportunities. Notice that loop nests with different trip counts can also be handled by splitting the largest nest such that one of the resulting nests has the convenient trip count.

Our idea is based on ranking Ehrhart polynomials. It has been shown in previous works dealing with spatial data locality optimization, that it is possible to compute an Ehrhart polynomial associated to a loop nest giving the rank of an iteration [5, 9]. These polynomials have specific properties as being necessarily monotonically increasing according to the lexicographic order of the loop indices, and also defining a bijection between iteration points and the interval of strictly positive integers between one and the total iteration count of the loop nest.

Since ranking Ehrhart polynomials define such bijections, the ability of inverting them would provide a way to retrieve the loop indices corresponding to the rank of an iteration. Hence at any iteration of a loop nest, it would be possible to compute, from the rank, the values of loop indices that would have been reached while running another nest. Thus, any nest could be run by another one, and any iteration space could be mapped onto another one, following the rank of the iterations. Hence this Section deals with the problem of inverting ranking Ehrhart polynomials.

Before proposing a general resolution, we first present a 2-dimensional example.

5.1 2-dimensional example

Consider the two loop nests in listings (1) and (2), where instructions\(k\)\((i1, i2)\) denotes the instruction block computed at iteration \((i1, i2)\). These loops have as respective ranking Ehrhart polynomials:

\[
P_1(i, j) = \frac{(i + 1)}{2} + j \quad \text{and} \quad P_2(i', j') = i' M_2 + j'
\]

for \((i = 1, i < N, i + +)\)

\[
\text{instructions}_1(i, j);
\]

for \((i' = 0, i' < M_1, i' + +)\)

\[
\text{instructions}_2(i', j');
\]

Taking the assumptions that both nests have the same iteration count and that there is no dependency between instructions\(_1\) and instructions\(_2\), we could merge the former loop nests and write (3).

\[
\text{for } (i' = 0, i' < M_1, i' + +) \quad \text{and} \quad (j' = 0, j' < M_2, j' + +) \quad \text{instructions}_2(i', j');
\]

However, we need to express indices \((i, j)\) as a function of \((i', j')\) in order to preserve the execution order of the block instructions\(_1\). More precisely, for each iteration number \(K\) in loop nest (3), we want to execute the \(K^{th}\) iteration of loop nest (1). This is why we must invert the ranking Ehrhart polynomial \(P_1\), to compute \((i, j) = P_1^{−1}(P_2(i', j'))\).

For any rank \(K\), we have to find a couple of indices \((i0, j0)\) such that \(P_1(i0, j0) = K\). The main idea is to cut the 2-dimensional problem into two one-dimensional problems.

Let us define \(Q_1(i) = P_1(i, 0) = \frac{i(i + 1)}{2}\). As ranking Ehrhart polynomials are (strictly) increasing, the following relation holds:

\[Q_1(i0) = P_1(i0, 0) \leq P_1(i0 + 1, 0) = Q_1(i0 + 1)\]

And, for the same reason, we know that index \(i0\) is unique on \(\mathbb{N}\). Let us now consider polynomial \(Q_1\) as a polynomial over \(\mathbb{R}\). By continuity of \(Q_1\) over \(\mathbb{R}\), there exists \(\alpha \in [0, 1]\) such that \(Q_1(i0 + \alpha) = K\). This shows that the equation \(Q_1(x) = K\) has at least one real solution. So we have to find \(x\) such that:

\[Q_1(x) = K \iff Q_1(x) − K = 0 \iff x(x − 1) = 2K = 0\]

Obviously, this last equation has two real roots:

\[x_1 = \frac{1}{2} \pm \sqrt{\frac{1 + 8K}{4}}, x_2 = \frac{1}{2} + \sqrt{\frac{1 + 8K}{4}}\]

To select the convenient root, we notice that for all \(K > 0\), \(x_1 \leq 0\). As \(i0 \geq 1\) (according to the loop bounds in (1)), \(i0 + \alpha = x_2\), and thus: \(i0 = \lfloor x_2 \rfloor\). We can now replace \(i0\) by its value in \(P_1(i0, j0)\):

\[P(i0, j0) = \frac{1}{2} \left( \left[ \frac{1}{2} + \sqrt{\frac{1 + 8K}{4}} \right] \left( \frac{1}{2} + \sqrt{\frac{1 + 8K}{4}} - 1 \right) + j0 \right)\]

and finally deduce \(j0\):

\[j0 = K - \frac{1}{2} \left( \left[ \frac{1}{2} + \sqrt{\frac{1 + 8K}{4}} \right] \left( \frac{1}{2} + \sqrt{\frac{1 + 8K}{4}} - 1 \right) \right)\]

The resulting code is shown in listing 4.
$K = 0$;
for ($\ell' = 0, \ell' < M_1; \ell' + +$) 
for ($j' = 0, j' < M_2; j' + +$) 
$K + +$;
$i = \text{floor}(\sqrt{((1 + 8 * K)/4) + 1/2});$
$j = K - i * (i - 1)/2;$
$\text{instructions}_1(i, j);$
$\text{instructions}_2(i', j');$
\(\text{(4)}\)

We now present the general case, which can be easily deduced from the 2-dimensional case.

5.2 General case

Without any loss of generality, we assume all loop indices lower bounds equal 0. We consider the $N$-dimensional ranking Ehrhart polynomial $P(i, j, k, ...)$, and for each $K$, we seek the tuple $(i_0, j_0, k_0, ...)$ such that $P(i_0, j_0, k_0, ...) = K$.

Similarly to the previous example, we start with the outermost loop index $i_0$. We define $Q_i(i) = P(i, 0, 0, ..., 0)$ and solve $Q_i(x) - K = 0$. Here is the only issue that differs from the 2D case: as we can't state that $Q_i$ is monotonically increasing on $\mathbb{R}_+$, we have to find a criterion to select the root giving the sought index.

First, we obviously eliminate complex and negative solutions, since $i_0 \in \mathbb{N}_+$, and consider $n \leq N$ positive real roots $(x_1, x_n)$. As we know that $i_0$ is unique, a way to select the convenient root is to check which $x \in \{x_1, ..., x_n\}$ satisfies:

$Q_i([x] = i_0) \leq Q_i(x) \leq Q_i([x] = i_0 + 1)$

However, this strategy is only applicable at runtime, and may add non negligible time overhead. A compile-time solution is to check if $Q_i$ is monotonically increasing on $\mathbb{R}_+$ by examining its derivative. If so, any root in $\{x_1, ..., x_n\}$ is suitable.

Once $i_0$ has been found, the process starts again with $Q_j(j) = P(i_0, j, 0, ..., 0)$, and so on until all indices have been computed.

6. CONCLUSION

We have proposed a new programming control structure called “multifor” and showed that it allows the polytope model to handle programming models that were not attainable directly before. Important related theoretical studies have still to be conducted, as dependency analysis between the for-loops composing a multifor-loop, or optimizing code transformations that considers interactions between the for-loops.

Many interesting extensions can also be studied as making header parameters, or instructions, dependent of several for-loop indices composing the same multifor-loop level, or defining non-invariant grains and offsets, or introducing conditional on the effective run of the for-loops, etc. In this paper, we showed that it may be possible to handle non-linear mapping of iteration spaces using inverted ranking Ehrhart polynomials.

The multifor structure can also be used as a representation model for some interacting mechanisms, as concurrent memory accesses, as it is done for sequential codes in [7].

We are planning to implement multifor structures in the Clang/LLVM compiler as an extension to C/C++.
